The objective of sensitivity analysis is to understand how the input uncertainty of a mathematical model contributes to its output uncertainty. In the context of a digital twin, sensitivity analysis is paramount for the automatic verification and validation of physical models, and can also be used as a decision support tool to determine on which parameter to invest more empirical effort. Yet, sensitivity analysis often requires making assumptions about the inputs such as probability distribution functions, as it is the case in variance-based methods, or relies on surrogate models that also introduce more assumptions, as in kriging or polynomial chaos. It can be the case that one cannot reliably assign probability distribution functions if the model is dominated by epistemic uncertainties, or the complexity of the model is such that surrogate models cannot accurately capture its behaviour.

We present a non-probabilistic sensitivity analysis method which requires no assumptions about the input probability distributions: the uncertainty in the input is expressed in the form of intervals, and employs the width of the output interval as the only measure, in the same way that interval analysis. As a positive by-product, the method also returns all the information that could be obtained with the reduction of the input interval to a single value, also called pinching. We use the Ishigami function as test case to show the performance of the proposed method, and compare it with Sobol indices.

1. Introduction

Prediction is inherent in science, because prediction is essential to test theories and their consequences. Thanks to the power of modern computation, the prediction of natural phenomena represented by mathematical models can now be tested at unprecedented scales. Digital twins attempt to exploit this advantage by modelling physical systems and allowing their evaluation via simulation, as these systems are often technically and economically prohibitive to operate in the physical world (Wagg et al. (2020)). However, digital twins are often so complex that it is not possible to infer

their prediction from experience and judgement alone. Therefore, it is desirable to verify and validate the prediction of these models without having to rely on subjectivity (I et al. (2020)). Sensitivity analysis can help with this task, by indicating what model parameters are responsible for the prediction of the model, and how that prediction depends on them (Saltelli et al. (2004)).

Generally, sensitivity analysis methods fall within three categories: derivative-based, distribution-based, and regression-based Razavi et al. (2021). Derivative-based approaches attempt to compute the derivative of the model functions,

either analytically or numerically, and measure the change in the output when the inputs are perturbed around a base point ([reference]). Distribution-based methods, such as Sobol' indices, decompose the output variance and assigns the partitions to the input variances, indicating how much of the output variance is caused by each input variance (Saltelli et al. (2010)). Lastly, regression-based approaches employ correlation coefficients, regression coefficients, or other machine learning methods (Sudret (2008)).

However, these approaches present some limitations that can make them unsuitable in certain cases. For instance, the analytical description of the functions in the model are not always available, since it is not uncommon to deal with black-box models or models with too many functions that make impractical or difficult their analytical derivation. Also, derivative-based methods require defining a base point for each input parameter, and a perturbation size. It is not rare to find a situation where there is not consensus about those elements. A similar argument can be made for distribution-based methods, which require a precise definition of the probability distribution functions of the model input parameters. Lastly, to successfully apply regression-based methods, it is necessary to know the behavior of the model under investigation, which is not always known. For example, partial correlation coefficients assume model linearity, or monotonicity in the case of partial rank coefficients (Saltelli and Marivoet (1990)). For these reasons, it is desirable to find a sensitivity analysis method that:

- (1) Does not require knowing the analytical description of the model functions.
- (2) Does not require defining base values for any input parameter.
- (3) Does not require to assume the input parameters follow a precise probability distribution function.
- (4) It is independent of the model behavior.

This paper attempts to present an interval-based global sensitivity analysis method that fulfills these requirements. Section 2 introduces some basic concepts in interval uncertainty propagation

which are required to perform the analysis. In Section 3 it is explained how the sensitivity indices are calculated in the interval approach, and the pinching measure that can be calculated additionally. Lastly, Section 4 compares the performance of the interval-based method against Sobol' indices in two test cases (Ishigami function and a basic physics problem), followed by the conclusion in section 5.

2. Interval Analysis

With interval analysis is possible to set bounds to the output of a model function. When capturing the rigorous enclosure of a model output one can know with certainty what the model represents, and decide whether it adequately depicts reality or not. Also, expressing parameter uncertainties in the form of intervals has the advantage of requiring no assumptions about the uncertainty, making intervals ideal to capture epistemic uncertainty.

The two main methods to compute with intervals are interval arithmetic and sampling. In the former, the mathematical operations are replaced to account of intervals as in [REF walley]. This method requires access to the analytical description of the models (i.e. source code) to make them suitable for interval arithmetic. Sampling methods, on the other hand, do not require to adapt the source code for interval arithmetic. A typical sampling procedure begins assuming uniform distributions for the uncertain parameters, performing the sampling using the Latin Hypercube algorithm, and extracting the minimum and maximum of the outputs of interest (i.e. their interval) [ref Helton]. Some of the drawbacks of the sampling methods are that the sampling algorithm could introduce unexpected correlations in the inputs [ref saltelli], and the output interval is an inner approximation instead of an outer approximation

(when quantifying uncertainty, it is better to be safe than sorry).

The sensitivity analysis presented in this paper can be applied with both methods of uncertainty propagation, employing the widths of the input and output intervals as the only required measures. Therefore, it can be used with black-box or sophisticated models that cannot be adapted to work with interval arithmetic (and therefore the uncertainty propagation has to be performed via sampling), or with models which already adopt interval arithmetic.

3. Interval-Based Sensitivity Index

The proposed sensitivity index captures the dependence of the model output on the inputs measuring the area described by these. Figure X serves as an illustrative example. It shows the scatterplots of the evaluation of a black-box function $y = f(x_1, x_2)$ with $x_1 \in [-5, 5]$ and $x_2 \in [-5, 5]$, with samples generated using Latin Hypercube sampling. As explained in [REF Helton Davis], scatterplot visualization is a straightforward qualitative method of inspecting dependencies in model functions. In this example it is possible to see how y has a linear dependence with x_1 , but shows little or no dependence with x_2 . The objective is to turn this qualitative *intuition* into a measurement.

The dependence can be captured measuring the area described by the scatterplot, and comparing it to the box defined by $(y, \bar{y}) \times (x_i, \bar{x}_i)$. If the measured area equals to the box, then it can be said that the output has no dependence on that input (as occurs for x_2 in Figure X). If the measured area has a value of 0, it means that the output is determined by that input. Then, any

other degree of dependence will fall in between these two extreme cases (as in x_1 in Figure X). It is important to note that the measurement of the area will be an approximation of the actual area, being a consequence of the sampling method or the subintervalization if interval arithmetic is employed to solve the model functions.

The sensitivity index is calculated with the following formula:

$$S_i = 1 - \frac{\sum_n^N (x_i, \bar{x}_i)_n \times (y, \bar{y})_n}{(y, \bar{y}) \times (x_i, \bar{x}_i)} \quad (1)$$

where N is the total number of subintervals. Therefore, S_i is a sensitivity index ranging from 0 (i.e. y is independent of x_i) to 1 (i.e. y is determined by x_i).

The area can be calculated with two different methods depending on whether interval arithmetic was employed to calculate the functions or it was done through sampling. In the case of interval arithmetic the calculation is straightforward as the subintervals can be recycled and the boxes described by these can be easily computed, as in Figure X. On the other hand, if sampling methods were chosen, then the area can be calculated employing an integration method similar to the trapezoidal rule: a step size is defined to sweep through subintervals of x_i in the data, the minimum \underline{y} and maximum \bar{y} is returned for each subinterval, and the box is computed as usual. The main drawback of the integration method is that a step size has to be defined manually, and the impact of this parameter on the proposed sensitivity analysis method has not been studied yet. However, the authors guess that since the method is similar to the trapezoidal rule, it should be possible to place error bounds on the accuracy of the sensitivity index.
